Relationship between plasma cell levels and profile of bronchoalveolar lavage fluid in patients with subacute extrinsic allergic alveolitis

M Drent, SjSc Wagenaar, H van Velzen-Blad, P G H Mulder, H C Hoogsteden, J M M van den Bosch

Abstract

Background—Plasma cells are usually absent in bronchoalveolar lavage (BAL) fluid. Extrinsic allergic alveolitis is associated with increased numbers of T and B lymphocytes in BAL fluid, as well as the presence of a few plasma cells. The aim of this study was to investigate whether there is a relationship between the presence of plasma cells and other cells, and immunoglobulin levels in BAL fluid of patients with extrinsic allergic alveolitis.

Methods—Thirty non-smoking patients with extrinsic allergic alveolitis who had a bronchoalveolar lavage 2–7 days after their last exposure to the causative antigen were selected, retrospectively.

Results—Patients suffering from extrinsic allergic alveolitis with plasma cells in the BAL fluid (n = 18) had increased absolute numbers of lymphocytes, eosinophils and mast cells, a decreased percentage of alveolar macrophages and lower CD4/CD8 ratio, as well as higher immunoglobulin levels, when compared with patients with extrinsic allergic alveolitis having no plasma cells in the BAL fluid (n = 12).

Conclusions—The results suggest a relationship between the presence of plasma cells and the other constituents in BAL fluid and a more intense alveolitis. In addition there was a positive relationship between the number of plasma cells in BAL fluid and immunoglobulin levels. These data support the concept of local production of immunoglobulins by plasma cells in the lung following antigen exposure in susceptible individuals.

The lung is capable of local immunological reactions by cell mediated as well as antibody mediated mechanisms. In interstitial lung diseases bronchoalveolar lavage (BAL) has become an important method of gaining information about disease processes in the lung. Extrinsic allergic alveolitis is initiated by repeated exposure to specific antigens in susceptible individuals. The immunological mechanisms underlying the pathological changes in the lung appear to be related to the dose of the causative antigens and the duration of exposure. In extrinsic allergic alveolitis initial non-specific inflammation is followed by sensitisation causing a granulomatous inflammatory response modulated by T cell and macrophage derived cytokines. This initial phase—that is, immediately after antigen inhalation—is characterised by an increase in the number of neutrophils in BAL fluid. In the subacute phase, 2–7 days after antigen exposure, the numbers of CD8+ lymphocytes and natural killer cells are increased. A few plasma cells are occasionally found in the BAL fluid, but are not generally found in peripheral blood or BAL fluid. If present in BAL fluid, B lymphocytes vary in maturation from small lymphocytes to mature plasma cells, supporting the concept that antigen specific B lymphocytes enter the immunised lung (possibly as lymphoblasts) and mature to plasma cells. Moreover, plasma cells in BAL fluid render allergic or inflammatory processes with an antibody mediated component highly likely. In addition, immunoglobulin levels in BAL fluid are elevated because of antigenic stimulation in patients with extrinsic allergic alveolitis compared with control subjects. These high immunoglobulin levels may be caused by an increase in pulmonary vascular permeability, or local production of immunoglobulins, or both. Plasma cells synthesise and secrete immunoglobulins but no relationship has been shown between plasma cells and immunoglobulin levels in BAL fluid.

In this study we have investigated differences between the profile of the BAL fluid in patients with extrinsic allergic alveolitis, with or without plasma cells, and the relationship of plasma cells with immunoglobulin levels in the lavage fluid.

Methods

Patients and Controls

Samples of BAL fluid obtained from patients suffering from extrinsic allergic alveolitis (n = 67; 59 non-smokers and eight smokers) during a 10 year period between 1980 and 1990 were studied. The patients with extrinsic allergic alveolitis presented with generalised constitutional and pulmonary symptoms—that is, cough, dyspnoea, and sometimes fever and chills. Although the symptoms were mostly transient, exacerbations occurred with repeated exposure to the causative antigen. The diagnosis of extrinsic allergic alveolitis was made from clinical information, chest radiology, the presence of serum antibodies
(precipitins, table 1) against the suspected antigens in peripheral blood, pulmonary function tests, and disappearance of symptoms after avoidance of antigen exposure. An open lung biopsy was performed in five patients without sufficient clinical criteria to make a definitive diagnosis. To exclude any influence of smoking on the profile of the BAL fluid only non-smoking patients (n = 59) were studied, all of whom had been frequently exposed to birds including pigeons, parrots, budgerigars, or canaries (table 1). No patient was on corticosteroid treatment before or at the time of the lavage. The patients were divided into four categories based on the time period between the presumed termination of antigen exposure and the lavage: group 1, <24 hours; group 2, 2–7 days; group 3, 8–30 days; group 4, 1–12 months. The patients with extrinsic allergic alveolitis last exposed 2–7 days before BAL (group 2; n = 30) having the highest number of plasma cells in their lavage fluid were further divided into two subgroups according to the presence or absence of plasma cells in the lavage fluid (table 1) and form the basis of this study.

A control group of 28 non-smoking healthy volunteers with no contact with extrinsic allergic alveolitis inducing antigens was also studied (table 1). This study was approved by the ethical committee of our hospital.

**BRONCHOALVEOLAR LAVAGE**

BAL was performed during fibreoptic bronchoscopy. Following premedication with atropine and local anaesthesia of the larynx and bronchial tree with tetracaine 0.5%, the right middle lobe was lavaged with four aliquots each of 50 ml sterile saline (0.9% NaCl) at room temperature. Simultaneous peripheral blood samples were taken.

The recovered BAL fluid was kept on ice in a siliconised specimen trap and separated from its cellular compounds by centrifugation (5 minutes at 350g). Supernatants were directly stored at −70°C after additional centrifugation (10 minutes at 1000g). Cells were washed twice, counted, and suspended in minimal essential medium (MEM; Gibco, Grand Island, New York, USA) supplemented with 1% bovine serum albumin (BSA; Organon, Teknika, Boxtel, The Netherlands).

Preparations of cell suspensions were made in a cytocentrifuge (Shandon). Cytospin slides were stained with May–Grünwald–Giemsa (MGG; Merck, Darmstadt, Germany) for cell differentiation and at least 1000 cells were counted. Morphologically, plasma cells were identified in a routine MGG stained slide by light microscopy. Only mature plasma cells recognised by an eccentric nucleus with a large amount of basophilic cytoplasm were included.

If more than 15% of lymphocytes were present, T cell (sub)populations were determined. Total T cells and subpopulations were recognised by staining with monoclonal antibodies CD2(OKT11), CD3(OKT3), CD4(OKT4), and CD8(OKT8) from Ortho Pharmaceuticals (Beersel, Belgium). Identification of T cells reacting with monoclonal antibodies was performed by means of a conventional indirect immunofluorescence technique using FITC-labelled goat antimouse (GAM) immunoglobulin (Nordic Immunological Laboratories, Tilburg, The Netherlands and Central Laboratory of the Netherlands Red Cross Blood Transfusion Service (CLB), Amsterdam, The Netherlands). Albumin determinations were performed according to the modified adaptation of the bromocresol purple dye binding method. Albumin concentrations in serum and lavage fluid were expressed in g/l and mg/l, respectively.

Immunoglobulin concentrations (IgM, IgG, and IgA) in BAL fluid were measured by an enzyme linked immunosorbent assay (ELISA) method; microwells were coated with a rabbit antihuman isotype antiserum [anti-IgM, (CLB, Amsterdam, The Netherlands), anti-IgG and anti-IgA (Dako, Glostrup, Denmark)]. Bound immunoglobulins from BAL fluid were visualised with a horseradish peroxidase labelled rabbit antihuman immunoglobulin antisera [with anti-IgA, -IgG, -IgM, -kappa, -lambda reactivity (Dako, Glostrup, Denmark)] and a chromogenic substrate orthophenylen diamine (OPD; Baker Chemicals BV, Deventer, The Netherlands). Immunoglobulin concentra-
Patients with extrinsic allergic alveolitis who underwent BAL within 2–7 days of antigen exposure (group 2) showed the highest percentage of plasma cells in the BAL fluid (table 1). Moreover, this largest subgroup (n = 30) contained most patients with plasma cells in the lavage fluid (n = 18). Furthermore, in this subgroup of patients the lowest value of plasma cells in the lavage fluid was 0.1% and the highest was 3.9% in one patient who had a lavage five days after antigen exposure. In none of the groups studied were plasma cells found in peripheral blood. In the patients in group 2 with plasma cells the total cell count (p < 0.01), and the absolute and relative number of lymphocytes were increased (p < 0.005), and the percentage of alveolar macrophages was decreased (p < 0.005) compared with patients without plasma cells (table 2). The absolute number of eosinophils and mast cells were higher in the patients with plasma cells (p < 0.05) than in those without (table 2). Both groups had an increased total cell count (p < 0.001), absolute and relative number of lymphocytes (p < 0.001), neutrophils (p < 0.005), eosinophils (p < 0.01), and mast cells (p < 0.005), and a decreased relative number of alveolar macrophages (p < 0.001) compared with the control subjects.

The patients with plasma cells had a lower percentage of CD4+ T cells (p < 0.05) and a significantly lower CD4/CD8 ratio (median 0.7; range 0.4–3.0) (p < 0.05) than the patients without plasma cells (median 1.9; range 0.5–3.9) (table 3). The measured percentages of T cells and T cell subpopulations of both patient groups (with and without plasma cells) showed significant differences when compared with the control group in whom T cell (sub)population determinations were performed (n = 6; p < 0.01), except for the percentage CD4+ T cells and CD4/CD8 ratio. The percentage CD4+ T cells was higher in the patients without plasma cells than in the control subjects (p < 0.05) and patients with plasma cells (p < 0.05). The CD4/CD8 ratio was lower in the patient group with plasma cells than in the control group (p < 0.01). In BAL fluid of patients with plasma cells the ratio of IgG to albumin was higher (2.3 to 0.95, p < 0.05); the ratios of IgM and IgA to albumin in the lavage fluid tended to be higher than in the patients without plasma cells. The immunoglobulin levels and their ratios to albumin in BAL fluid were higher in both patient groups than in the control group (p < 0.01) (table 4).

STATISTICAL ANALYSIS

To investigate whether there were significant differences between the profile of BAL fluid of patients suffering from extrinsic allergic alveolitis, with or without plasma cells, the Mann-Whitney U test was used. Spearman rank correlation coefficients were estimated in order to test against a monotonic relationship between the absolute and relative number of plasma cells in BAL fluid on one hand, and the levels of albumin, IgM, IgG, IgA, and the ratios IgM to albumin, IgG to albumin, and IgA to albumin in BAL fluid on the other. A p value of <0.05 was considered to be significant.
showed a significant monotonic relationship between the absolute and relative number of plasma cells in BAL fluid, and the levels of immunoglobulins and their ratios to albumin (Table 5).

The light microscopic evaluation of the five patients who underwent open lung biopsy showed many plasma cells within the alveolar interstitium in all specimens, irrespective of the presence or absence of plasma cells in the lavage fluid.

Discussion
Extrinsic allergic alveolitis is thought to result from a combination of a type III immune complex and a type IV cell mediated immunological reaction, although the mechanism remains unknown. Plasma cell derived antibodies have been found in the serum and BAL fluid of patients with extrinsic allergic alveolitis. Under normal circumstances plasma cells, known as tissue cells, are not found in BAL fluid nor in peripheral blood. However, in the alveolar interstitium of the immunised lung plasma cells frequently occur. Recently we have shown the presence of plasma cells in the lavage fluid of patients with extrinsic allergic alveolitis and other antibody mediated inflammatory processes of the lung such as drug induced pneumonitis. This uncommon motile behaviour of plasma cells can probably be explained by damage of the alveolar membranes and non-specific changes in vascular permeability produced by antigen exposure. In addition, the presence of plasma cells in lavage fluid was considered to be a feature of recent antigen exposure, suggesting an active alveolitis.

In the present study the cellular profile of the BAL fluid differed significantly between patients with extrinsic allergic alveolitis last exposed 2-7 days before the lavage (group 2; n = 30) who had plasma cells in the lavage compared with those who did not. The patients with plasma cells had an even more active alveolitis with an increased total cell count and increased absolute and relative numbers of lymphocytes. In addition, the pattern of T cell subpopulations differed between both groups. The CD4/CD8 ratio in BAL fluid was decreased in the group with plasma cells suggesting a more active alveolitis in these patients. This finding agrees with Trentin et al who also found a more active alveolitis in patients suffering from extrinsic allergic alveolitis with a decreased CD4/CD8 ratio, although in their study no differentiation was made between patients with or without plasma cells in the lavage fluid. Trentin et al also showed a shift from the CD8+ predominant cellular profile of BAL fluid of patients with extrinsic allergic alveolitis towards the normal CD4+ predominant profile after removal from exposure to the causative antigen, suggesting a change in the alveolitis. In our study we found that the CD4+ T cells predominated over CD8+ T cells in the patient group without plasma cells, whereas the percentages of CD4+ and CD8+ T cells were equal in the patients with plasma cells in the lavage fluid.

A decrease in CD8+ T cell suppressor activity in extrinsic allergic alveolitis may cause augmented CD4+ T cell reactions. Activated CD4+ T cells have been implicated in the cellular and humoral immune responses to antigenic stimulation by the production of cytokines. These cytokines recruit alveolar macrophages (gamma interferon), neutrophils (interleukin (IL)-8), eosinophils (IL-5), mast cells (IL-3), and natural killer cells (IL-2) into the alveolar interstitium in a cascade of events causing CD4+ T cells, especially IL-5 producing CD4+ T subsets, may be involved in the mediation of eosinophilic recruitment into the airways, as suggested by the preventive effect of depletion of CD4+ T cells, but not of CD8+ T cells, on antigen induced eosinophilic infiltration in mice. We found an increase in the absolute number of eosinophils in the group with plasma cells compared with patients without plasma cells, although the absolute numbers of CD4+ T cells were equal in both groups (data not presented). This difference in eosinophilia might be caused by different subpopulations of CD4+ T cells causing different IL-5 production. Like Laviolette et al we also found an increased absolute number of mast cells in both groups, particularly in the patients with extrinsic allergic alveolitis with plasma cells. This might be caused by activation of the same CD4+ T cell subpopulation, as this subpopulation of T cells produces both IL-3

Plasma in bronchoalveolar lavage fluid with extrinsic allergic alveolitis

These findings, and those reported in our study, show that immunoglobulin levels and their ratios to albumin in BAL fluid are positively related to the presence of immunoglobulin producing plasma cells in lavage fluid. In this study patients without plasma cells also showed increased levels of immunoglobulins, the levels among patients with plasma cells being higher than in patients without plasma cells. These higher immunoglobulin levels in BAL fluid of patients with plasma cells might be the result of the local production of immunoglobulins by plasma cells in BAL fluid, in addition to enhanced diffusion from the interstitium due to destruction of the basement membrane.

In conclusion, patients suffering from extrinsic allergic alveolitis with plasma cells in BAL fluid show signs of a more active alveolitis. They have increased absolute and relative numbers of lymphocytes, higher absolute numbers of eosinophils and mast cells, higher immunoglobulin levels and IgG to albumin ratios, as well as a decreased CD4/CD8 ratio in comparison with patients without plasma cells in BAL fluid. In addition, there is a positive relation between the number of plasma cells in BAL fluid and immunoglobulin levels. These data promote the concept of local production of immunoglobulins by plasma cells within the lung following antigen exposure in susceptible individuals. Studies on the relation of time elapsed between antigen exposure and BAL procedure, and the production by plasma cells of IgM, IgG, and IgA, are currently being conducted.

We gratefully acknowledge Dr Michaela Diamant and Dr Henk van Loveren for their advice and critical comments during the preparation of this manuscript, Mona Donckerwolcke-Bogaert and Els Tiensman for their laboratory work and their help in collecting the data. This study was supported by a grant from Glaxo BV, The Netherlands.

Relationship between plasma cell levels and profile of bronchoalveolar lavage fluid in patients with subacute extrinsic allergic alveolitis.
